Circumstellar Disks in pre-Main-Sequence Stars

Antonella Natta

Osservatorio di Arcetri, INAF, Largo Fermi 5, I-50125 Firenze, Italy

Abstract. This review covers the properties of disks around pre-main-sequence stars. It is at this time in the evolution that planets form, and it is important to understand the properties of these disks to understand planet formation. I discuss disk shapes, masses and temperatures, the properties of the host stars, disk lifetimes and dissipation processes. Finally, evidence of grain growth during pre-main-sequence evolution is briefly summarized.

1. Introduction

Circumstellar disks surrounding pre-main-sequence (PMS) stars of solar and intermediate mass have been known and studied, firstly indirectly, through their unresolved emission in the near and far infrared and at millimeter wavelengths, and more recently by direct imaging in the optical, near infrared and millimeter. Excellent reviews of a number of topics concerning disks in the pre-main-sequence phase of the evolution can be found in *Protostars and Planets IV* (Mannings, Boss & Russell eds. 2000).

The formation of circumstellar disks is considered a necessary consequence of the process by which a molecular core collapses to form a star (see Shu et al. 1987). However, disks live behind this first period during which stars form. PMS stars, which have accreted most of their final mass and dispersed most of their parental cloud, are still surrounded by disks. We usually assume that such disks contain gas and dust with properties that do not differ much from those of the gas and dust in the parental core.

As the star contracts toward the main sequence, the disk ages. A variety of processes change the properties of the gas and dust in the disk, and finally lead to disk dissipation. One such process, but not the only one, is the growth of dust grains and the formation of planets. Planets form in disks around PMS stars, and the properties of planetary systems depend to a large degree on the properties of their birthsites, the PMS disks, and on how they change with time.

In this review, I will first summarize what we know of the properties of PMS disks around solar-type stars. I will then address the question of what kind of stars have disks during their PMS phase, and how these disks evolve. Finally, I will discuss the evidence for grain growth during the PMS disk lifetime.

2. Properties of disks around PMS stars

Disks have been detected around PMS stars with masses between about 0.5 and 5 $M_{\odot}$ (T Tauri stars or TTS and Herbig Ae stars or HAe). Some of their properties are known from observation and comparison with theoretical models. However, there are still some important parameters (for example, the run of the surface density with radius) which are not well constrained by the existing observations. Also, as often, new and improved observations reveal unexpected and complex properties, that need then to be taken into account.

2.1. Shape

An important recent result is the direct observation of disk shape by means of the HST observations of disks driving HH jets (see McCughrean, Stapelfeldt & Close 2000 and references therein; the first image was obtained by Burrows et al. 1996 for the object HH30). HST images map the shape of the disk surface seen in scattered stellar light and show that the disks are “flared”, i.e., that the ratio H/R of the scale height over the distance from the star is an increasing function of R . This is expected for gaseous disks in hydrostatic equilibrium (Kenyon & Hartmann 1987), and in fact detailed analysis of the HST scattered light images has shown good quantitative agreement between observations and theory. In a disk in hydrostatic equilibrium, the scale height H at each radius is determined by the equilibrium between the local pressure and the gravitational field of the central star:

$$\frac{H}{R} = \left(\frac{T_d}{T_c}\right)^{1/2} \left(\frac{R}{R_{star}}\right)^{1/2} \quad (1)$$

where T_d is the disk temperature at R (assumed isothermal in the vertical direction) and T_c is a measure of the gravitational potential of the star:

$$T_c = \mu_g \frac{GM_{\star}}{kR_{\star}} \quad (2)$$

where μ_g is the mean molecular weight of the disk material, $M_{\star}$ and $R_{\star}$ are the mass and radius of the central star, respectively. If the disk mass is dominated by gas, then H/R is about 0.03 at 1 AU, and 0.1–0.15 at 100 AU (for a typical TTS; Chiang & Goldreich 1997). On the contrary, if the disk mass is dominated by dust, μ_g is much larger and H/R becomes negligibly small. Dust disks are expected to be geometrically flat, rather than flared.

During the PMS evolution, most of the disk heating is caused by irradiation from the central star, and the shape of the disk affects its temperature profile, and, therefore, its spectral energy distribution (SED). Flared disks intercept a larger fraction of the stellar radiation at large radii than flat disks, so that their SED is a flatter function of wavelength (Kenyon & Hartmann 1987; Chiang & Goldreich 1997). Most PMS stars have SEDs typical of flared disks (see, for example, Chiang et al. 2001; Natta et al. 2001), and we can reasonably conclude, even when direct images are not available, that they must have gas-rich disks. Self-consistent calculations of the structure of disks in hydrostatic equilibrium and their SEDs have been computed, e.g., by D’Alessio et al. (1998, 1999, 2001) Bell (1999), Dullemond, van Zadelhoff & Natta (2002).

Note that both observations, namely the flared shapes seen in scattered light and the flat SEDs, require not only gas-rich disks, but also that relatively small (sub-micron) grains are well mixed to the gas at all vertical heights, i.e., that dust sedimentation and grain growth have not proceeded very far. It is interesting to note that there are some objects with SEDs typical of flat disks (Meeus et al. 2001) or, at least, significantly less flared than predicted by hydrostatic equilibrium models (Chiang et al. 2001; D'Alessio et al. 2001). It is possible that in these systems grains have started settling toward the disk midplane, separating from the gas. The gaseous disk is still flared, but the dust disk is much flatter. It seems unlikely, given that there is some indication of gas accretion onto these stars, that they represent an even older stage of the evolution, when gas has dissipated and dust dominates the disk mass. These “steep SED” objects deserve to be explored in more detail.

2.2. Mass

Another very important quantity for planet formation studies is disk mass. It is reasonably easy to measure the mass of the dust in the disk, from the flux at some long wavelength (typically, in the millimeter) where the emission is very likely optically thin. In its simplest formulation, the dust mass is given by the expression:

$$M_{dust} = D^2 \frac{F_\nu}{\kappa_\nu B_\nu(T_{dust})} \quad (3)$$

where κ_ν is the dust opacity at the observed frequency, T_{dust} the dust temperature (typically, 10-20 K in TTS), D the distance and F_ν the observed flux. This expression can be improved using more detailed disk models, which take into account the temperature and surface density profile by fitting, for example, the spectral energy distribution over a wide range of wavelengths. For sources of known distance, the main uncertainty is due to the uncertainty on the dust opacity. Most authors assume $\kappa_{1.3\text{mm}} = 0.5 - 1 \text{ cm}^2/\text{g}$ of dust, but this value is very uncertain if significant grain growth has occurred (see Beckwith, Henning & Nakagawa 2000).

Once the dust mass has been determined, it is necessary to correct for the gas-to-dust mass ratio. In disks, this is uncertain, and one assumes a value of 100, which is typical of the interstellar medium. Disk masses derived in this way range roughly from 0.003 to 0.3 $M_\odot$, with a large spread even for stars of similar properties. Fig. 1 shows an updated version of the compilation of Natta, Grinin & Mannings (2000).

Direct determinations of the gas mass exist for some objects, but they do suffer from large uncertainties. A number of PMS disks have been observed in gas tracers such as CO. Gas masses derived from CO, using standard values of the conversion factor CO/H₂, are much lower (by orders of magnitude) than those obtained from dust (Guilloteau & Dutrey 1998; Mannings & Sargent, 1998, 2000). It is likely that the molecular tracers are affected by depletion onto grains (see, for example, van Zadelhoff et al. 2001), and, in some cases, by optical depth effects. Observations of several molecular species and transitions can be used to constrain the local gas density and to infer from that the disk mass. This has been done so far for only two objects (Dutrey, Guilloteau & Guelin 1997), and showing that depletion occurs in several molecules. Recently, some observations

Figure 1. Top panel: disk masses (gas+dust, assuming a gas-to-dust mass ratio of 100) derived from millimeter fluxes are plotted as function of the stellar mass. Triangles are upper limits, dots detections; filled symbols are interferometer data, open symbols are single-dish measurements. The lower panel plots the ratio of the disk to the stellar mass. Data from the compilation of Natta et al. (2000), with some additional points for early B stars from OVRO (Mannings et al. 2000, personal communication) and IRAM/PdB (Fuente et al. 2001).

of mid-infrared H_2 lines have been obtained with ISO for a handful of TTS and H Ae stars, and the results seem to indicate a better agreement with dust-derived disk masses (Thi et al. 2001); however, the observed H_2 lines do not trace the cold gas, which is likely to dominate the mass, so that large extrapolations are required. Also, in spite of the careful selection of objects aimed at excluding those with surrounding low-density gas, there is some doubt that the H_2 emission has its origin in the disk, since ground-based observations obtained with a beam much smaller than that of ISO do not detect any comparable emission (Richter & Lacy, this conference). Future space missions, like SIRTf, will certainly clarify this issue.

2.3. Size

Disk sizes can be directly obtained from images at various wavelengths. As one might expect, the result depends on the tracer and on the wavelength of the observations. Millimeter interferometers (PdB, OVRO, VLA at 7mm) have been used to map the outer disk both in the dust continuum emission and in molecular gas, mostly CO. Dust millimeter emission is generally rather compact; when resolved, disks have radii (HWHM) of 50–100 AU (see Wilner & Lay 2000 and references therein and Mannings & Sargent 1998, 2000). Maps in the lines of various CO isotopes show larger radii, typically a few hundred AU (Koerner & Sargent 1995; Dutrey et al. 1996; Mannings & Sargent 1998, 2000). The HST images in scattered light give similar sizes, but some disks in Orion seen as silhouettes against the luminous background of the Orion nebula can be as large as 1000 AU (McCaughrean & O’Dell 1996). It is likely that these apparent differences result from a combination of the dependence of the specific tracer on the distance from the star with the sensitivity of the adopted technique.

To summarize, we can safely say that there is clear evidence of gas in Keplerian rotation on scales of few hundred AU (see Dutrey 2000). In some objects, matter in a flattened structure is present even at larger distances from the central star.

2.4. Temperatures

The disk thermal structure can only be derived by comparing observations with model predictions. In principle, we would like to know both dust and gas temperatures, which are coupled only in the high-density regions of the disk, and to determine for both the variation of T in the radial and vertical directions.

At the moment, the most abundant information is for the run of dust temperature with radius, which is obtained by comparing model predictions to measured SEDs. Most PMS disks are heated by irradiation from the central star, and dissipation of viscous energy may play a role, if any, only in the very inner disk (Calvet, Hartmann & Strom 2000). Therefore, to a good approximation the disk temperature T is proportional to the stellar temperature, ranging from about $1/2 T_\star$ near the star to about $0.01 T_\star$ at $10^3 R_\star$ (for flared disks), as shown in Fig. 2. This temperature is in fact an effective temperature, computed by balancing the absorbed and emitted energy at each radius. To zero order, the disk is isothermal in the vertical direction, so that it is generally assumed that T is the temperature of the disk midplane, where most matter resides.

Figure 2. Ratio of the disk temperature to the temperature of the central star as function of R/R_* . The two dot-dashed curves are for flared disks, one for a disk around a Herbig Ae star (dot-long dashed), the other for a disk around a M7 star (dot-short dashed). The figure shows also the temperature profile of a flat disk (solid line) and of the disk surface (dotted line); these two quantities, normalized to T_* , are practically independent of the central star.

However, simple considerations show that in an irradiated disk the surface is hotter than the midplane (Calvet et al. 1992, Chiang & Goldreich 1997), so that at each radius there is a vertical gradient of temperature, which does indeed affect the shape of the SED and produce dust emission features, as observed in most TTS and HAe stars (see, for example, Chiang & Goldreich 1997).

The gas temperature is likely to differ from the dust temperature as soon as the density drops below some critical value (typically, of order $10^4 - 10^5 \text{ cm}^{-3}$). This is likely the case in the surface layers of the disk, as well as in the disk midplane at large distances from the star. Since molecular excitation and chemistry in the disk depend on the gas temperature, predictions of the expected molecular line intensities depend on a good knowledge of the disk vertical structure and of the gas-dust thermal coupling. This is an area of fast progress, both theoretically and observationally, from which we can expect a wealth of results in the next few years.

One final point I would like to mention is that the thermal history of the disk material during the PMS life of the star can be very far from smooth, as high-energy flares, activity-related phenomena, shocks from residual accreting gas and winds take place. These aspects still need exploration.

3. The disks of Herbig Ae stars

One of the results of direct disk imaging is that PMS disks are not smooth, simple structures. They are perturbed by a large variety of effects (for example, dynamical perturbations by companions), in ways that can affect their evolution. Sometime, high-spatial resolution observations seem to conflict with our previous understanding of disks. Often, however, they may give us clues to long-standing puzzles, as in the case of disks around Herbig Ae stars.

All the isolated Herbig Ae stars, i.e., PMS stars of mass $2-3 M_{\odot}$ with little evidence of surrounding matter, have a strong IR excess, reminiscent in many ways of that observed in TTS. However, the origin of this emission has been at the center of a controversy, which began with the work of Hillenbrand et al. (1992) and lasted for many years (see Natta et al. 2000 for a summary). At the core of the discussion was the fact that these stars emit in the near-IR a significant fraction of their luminosity (up to 25%; see Meeus et al. 2001), with a peak at about $2-3 \mu\text{m}$ (the near-IR “bump”; Hillenbrand et al. 1992). These two properties (shape of the near-IR bump and energetics) are inconsistent with any standard disk model (either heated by viscosity or by irradiation from the star), and there have been various suggestions in the literature that in fact the IR emission of HAe stars is not due to matter in a disk but rather to a more spherical shell of dust (see, for example, Berrilli et al. 1992), possibly containing very small, transiently heated grains (Hartmann, Kenyon & Calvet 1993). Further doubts on the disk hypothesis were shed by the first near-IR interferometric observations published for some HAe stars (Millan-Gabet, Schloerb & Traub 2001), which show that the data are not consistent with the predictions of standard disk models, but suggest instead that the emission comes from a ring of dust at a distance from the star comparable to the dust sublimation radius (about 0.3 AU for the A0 star AB Aur).

Figure 3. The sketch on the left (from Dullemond et al. 2001) shows the proposed structure of Herbig Ae disks. Note the inner hole, where only optically thin matter exists, the rim, at the dust condensation radius, the shadowed region and the flared outer disk. The right panel shows the SED of the star AB Aur (from Natta et al. 2001). Triangles, dots and the thick line are the observed data. The thin solid line is the stellar photosphere, the dotted line is the SED of a flared, irradiated disk with no inner rim, and the dashed line shows the approximate contribution of the rim. The total fits the observation rather well.

Recently, it has been proposed that the IR properties of these HAe stars can be understood if one considers the modification to the inner disk structure introduced by dust sublimation. In a disk where the gas is optically thin to the stellar radiation, as is likely to be the case in most optically visible HAe stars where the accretion rate is very low (Grady, this conference), the condensation of dust at radii of few tenths of AU from the star forms an optically thick inner rim which is frontally heated by the star and is therefore hotter than the disk midplane. The disk “puffs up” and forms an inner rim (Natta et al. 2001), whose emission has the characteristics of the observed near-IR excess (see Fig. 3). The SED of puffed up disks has been computed self-consistently (Dullemond, Domink & Natta 2001) and fits very well the observations. Also, it is possible to explain with these models, the interferometry results, since the near infrared emission comes entirely from the inner rim.

A similar “puffing up” may occur also if there is a gap opened in the disk, for example by the formation of a planet (Sasselov & Lecar 2000). In this case also, the dust at the edge of the gap further from the star is exposed frontally to the stellar radiation and is therefore hotter than dust in the disk midplane at the same distance from the star. In a recent paper Calvet et al. (2002) model the disk of the nearby TTS TW Hya as having an inner gap and a puffed-up rim at about 3–4 AU from the star, possibly caused by a still growing protoplanet. As for the inner disks of HAe stars, interferometry in the near and mid-IR with the instruments soon coming on line, such as VLTI, will provide direct images of such structures.

4. Do stars of all masses have disks?

As I have already mentioned, most of our knowledge of PMS disks is restricted to stars in a range of mass roughly $0.5\text{--}5\ M_{\odot}$. It is worthwhile to explore disks around stars outside this range, much more and much less massive, and for a variety of reasons. One, and the most obvious, is that disks are the signpost of star formation via gravitational contraction of molecular cores; their presence can shed light on the stellar formation mechanism. There is, however, an additional reason to study disks around “extreme” objects, namely that the very different physical conditions expected in these disks can help clarify the various processes that control disk evolution, including planet formation.

4.1. Herbig Be stars

The process of formation of massive stars has been the center of a long-lasting debate (see Stahler, Palla & Ho 2000 for a review). As an alternative to gravitational collapse, where radiation pressure prevents the formation of stars above a certain mass, it has been proposed that massive stars form by coagulation of lower mass objects (Bonnell, Bate & Zinnecker 1998). One prediction of this mechanism is the lack of massive disks around massive stars.

It is very difficult to collect a significant sample of O stars where disks can be studied. The best one can do is to look at the most massive among Herbig Be (HBe) stars. They have masses of about $8\text{--}20\ M_{\odot}$ and are very young (less than few million years). These stars lack a PMS phase and when they become visible, they are already on the ZAMS (Palla & Stahler 1993). About a dozen have been observed with millimeter interferometers and only one (R Mon) has been detected. Fig. 1 shows that the derived upper limits to the ratio of the disk to stellar mass (assuming the usual factor 100 to convert from the observed dust mass to total mass) are significantly lower than the values of lower-mass stars. Early B stars reach the ZAMS with disks of relatively little mass, if any.

The conclusion that HBe stars never had disks is, however, premature. All evidence, including the presence of outflows and jets and tentative detection of disks in the embedded phase (see Kurtz et al. 2000), the distribution of the circumstellar gas in HBe stars of different age (Fuente et al. 2001, 2002), and the presence of extended dust structures around these objects (Natta et al. 1993, Di Francesco et al. 1998, Abraham et al. 2000) points to a fast evolution of the circumstellar matter. It seems likely that the HBe disks are quickly dispersed. I will come back to the HBe case in the following section.

4.2. Brown dwarfs

Recently, at the other extreme of the mass range, the formation process of brown dwarfs (BD) has become of interest, as more and more BDs are discovered in star forming regions. Formation theories alternative to collapse of a molecular core include the possibility that below a given mass, BDs form like giant planets in gravitationally unstable regions of circumstellar disks (Papaloizou & Terquem 2001), or that they are stellar embryos ejected from multiple systems (Reipurth & Clarke 2001; Bate, Bonnell & Bromm 2002). In both these alternative views, one expects only very small, short-lived disks, if any. The search for BD disks is producing some interesting results. Using near-infrared color-color diagrams, as

Figure 4. Spectral Energy Distribution of two BDs, one in Chamaelion I (left panel, mass about $0.02 M_{\odot}$ or 20 Jupiter masses; from Natta & Testi 2001) and one in ρ Oph (right panel, mass about 8-12 Jupiter masses; from Testi et al. 2002). Dots and the thick black line for #033 are observations. Thin grey lines show the predictions of irradiated disk models of various flavours: solid lines are for irradiated flared and flat disks extending to the stellar radius, dot-dashed line for a flared disk with an inner hole of about $3R_{\star}$. For Cha Ha1, only the flared disk with no inner hole is shown. To all models we have added the contribution of the photosphere.

for TTS, Muench et al. (2001) find that 63% of candidate BDs in the Trapezium cluster have disks. However, in the older region σ Ori (age 2–7 Myr), the same technique shows that no BD candidate has disks (Oliveira et al. 2002). Mid-infrared ISOCAM surveys have detected many candidate BDs associated with warm dust in star-forming regions (Persi et al. 2000, Bontemps et al. 2001). As for the Trapezium objects, the BD nature of the candidates needs to be confirmed spectroscopically. More detailed studies of individual objects (Natta & Testi 2001; Testi et al. 2002; Natta et al. 2002) selected among mid-IR sources in the young regions Cha I and ρ Oph have shown that there are bona-fide BD with excess mid-IR emission that can be modeled as being due to disks irradiated by the central object (see Fig. 4). These disks are optically thick at mid-infrared wavelengths, and in some cases (the two with the lowest mass in the sample), there is evidence that the disks have to be flared, i.e., gas-rich. The SIRTf/Legacy observations of star forming regions, with good wavelength coverage and sensitivity, should allow us to explore the properties of BD disks in detail.

5. Disk lifetime

The lifetime of PMS disks is a crucial parameter, since any planetary system must be formed before the disk dissipates. The current wisdom is that PMS disks live a few million years. This is based on near-IR surveys of TTS in a number

of young clusters of different age (see Alves et al. 2002), and, strictly speaking, refers only to the inner disk, which emits at those wavelengths. However, there is some evidence (which, however, should be re-discussed with the better statistics available today) that the process of disk dissipation, once started, occurs rapidly (few 10^5 yr; Skrutskie et al. 1990), and over a similar timescale at all radii (see, for example, Duvert et al. 2000), in both dust and gas.

There is evidence that disks around more massive stars have shorter lifetimes. We have already mentioned the case of HBe stars, but the trend of rapid evolution seems to extend to stars of lower mass (A and F), when statistical indicators are used. For example, in the Trapezium cluster Lada et al. (2000) find that only 42% of stars of spectral type OBA have a near-IR excess, versus an average 78%; in IC 348 Haish, Lada & Lada (2001) find that 0% of stars of spectral types BAF have excess, versus 54% of the total.

Although on average there is a clear trend of disk frequency with age, individual objects tell us a much more complex story. There are (relatively) old stars (age ~ 10 Myr) that still retain their PMS gas-rich disk (see, for HAe stars, Natta et al. 2000), and young objects that have already lost it, as is the case for many weak-line T Tauri stars (WTTS).

This is in fact not surprising, when we consider the variety of processes that can cause the dispersal of disks. Among them are processes intrinsic to the disk itself, such as viscosity and planet formation, and others that depend on the interaction of the disk with the central star, in particular with the radiation field and wind. The environment where the disk evolves is also important. For example, a nearby massive star may evaporate the disk, as in Orion, or destroy it by tidal interactions. Stellar encounters may destroy the disk, and dynamical interaction between the disk and possible companions may also dissipate it. It is also possible that stars are born with disks of different mass. If, for example, the measured spread of disk masses seen in Fig. 1 is intrinsic, we should expect a similar spread in disk lifetimes (more than a factor 100). It is not impossible that WTTS are objects born with disks at the lowest end of the mass spectrum, or that the only disks which live long enough to form planets are those at the upper end of the disk mass distribution. We do not know enough, at present, to have a clear understanding of these points, but they are certainly worth investigation in the future.

Disk dispersal processes have been described in detail by Hollenbach, Yorke & Johnstone (2000), and the effect on disks of dynamical processes is further discussed by Artimowicz in this conference. I will confine myself here to the case of Herbig Be star disks.

5.1. The case of Herbig Be disks

All disks evolve as matter is accreted inward and angular momentum is transported outward. This process is usually described in terms of viscosity, by which most of the mass accretes onto the star, while a very small fraction moves to infinity carrying the disk angular momentum. One of the characteristics of viscous evolution is that the disk radius increases with time, so that the viscous timescale of the outer regions, where at any given instant the mass resides, keeps increasing, and viscosity alone cannot explain the complete disk dissipation.

The disk evolution is also affected by the presence of the central star, which can cause photoevaporation of its surrounding disk. Evaporation by photoionization is irrelevant for TTS, and not very effective in HAe stars. In these objects, however, softer photons ($12 < h\nu < 13.6$ eV) can photodissociate and warm up the disk material and dissipate it in a manner similar to photoionizing photons. Also, flares and the UV radiation emitted in TTS by accretion shocks can erode the outer disk. Hollenbach et al. (2000) conclude that photodissociation may be able to dissipate the outer disks of TTS on timescales comparable to those observed.

The case of HBe stars is particularly interesting, since these stars have the shortest timescale for disk dissipation of all PMS stars (much less than 1 Myr). Even if one cannot exclude that other processes such as disk ablation by a stellar wind, may have an important role, it is possible to explain this evolution simply by the combined action of two processes, viscosity and photodissociation. Fig. 5 plots the viscous dissipation and photodissociation timescales for a B0 ZAMS disk. One can see that the outer disk (for R greater than about $1/3R_{cr} \sim 30$ AU, where R_{cr} is the radius at which the gravitation of the star balances the sound speed of the ionized disk material) evaporates very rapidly (in about 10^5 yr). The residual disk may then be destroyed by viscosity on a comparable timescale.

A combination of various processes is likely to occur in all stars, and may in fact determine the characteristics of disk dissipation. For example, Clarke, Gendrin & Sotomayor (2001) combine viscous evolution and photoevaporation by X-ray emission near the photosphere to explain not only the typical lifetimes but also the rapid transition of TTS from disk to diskless.

6. Grain growth in PMS disks

The last topic I want to discuss is that of grain growth in PMS disks. Growth from the typical size of grains in the ISM (roughly smaller than few tenths of microns) to much larger values is expected to occur in the denser layers of circumstellar disks during the PMS phase. This, if proved, would be a strong indication that the sequence of processes we think lead from typical PMS disks to planets is indeed occurring. However, a robust indication that PMS disk grains are growing has been elusive.

The argument in favour of large grains in the disk midplane is an old one, and is based on a very simple argument. Suppose that the long wavelength emission of a disk is optically thin, then the flux dependence on wavelength should mirror the opacity law. Namely, if α is the observed spectral index ($F_\nu \propto \nu^\alpha$) and the opacity can be expressed as $\kappa_\nu \propto \nu^\beta$, then one should have $\alpha = 2 + \beta$. As soon as the first submillimeter and millimeter observations became available, it was realized that TTS have lower values of α than more embedded young stellar objects (see Fig. 6). This result was interpreted as evidence for large grains in the TTS disk midplane, of sizes $>$ few millimeters. Note that this is not in contradiction with the presence of silicate emission features in the same objects, since such features are due to grains on the disk surface, and a grain size vertical stratification is expected. This argument, and its caveats, has been discussed, among others, by Beckwith et al. (2000).

Figure 5. Dissipation timescale for the disk of a B0 star as function of the disk radius. The lines refer to the photoevaporation caused by the radiation field of the central star (dot-dashed line) and viscosity (solid lines) for two different values of the viscosity parameter α , as labelled. The disk mass is $0.5 M_{\odot}$, about $0.03 M_{\star}$.

Figure 6. Spectral index from sub-millimeter and millimeter photometry for a sample of TTS (slashed hatching) and more embedded YSOs (back-slashed hatching); data from Beckwith & Sargent (1991) and Moriarty-Schieven et al. (1994).

The main weakness of this result lies in the assumption that the disk emission is optically thin. Indeed, if this is not true and the disk remains optically thick over the whole observed wavelength range, its emission would be that of black-body ($\alpha = 2$), mimicking the characteristics of extremely large grains with $\beta=0$. This effect has been investigated in detail for few stars, using interferometric data between 1.3mm and 7mm (Testi et al. 2001). The results are shown in Fig. 7 for four stars.

It is clear that even for the extreme case of UX Ori, which has $\alpha_{1.3mm-7mm} = 2 \pm 0.2$, the observations can be fitted by a very optically thick small disk, or by a larger, optically thin disk with centimeter size grains (pebbles), having $\beta \sim 0$ up to a wavelength of 7mm. Of the four stars, CQ Tau has been marginally resolved both at 1.3mm (Dutrey, personal communication, quoted in Natta et al. 2001) and at 7mm (Testi et al., in preparation) and has a rather small disk (R about 50 AU). HD 163296 has been marginally resolved by OVRO (Mannings & Sargent 1997) with a size of about 100 AU (FWHM) and an inclination angle of 58 degree. Well resolved images at 7mm are necessary to discriminate between different models.

So far, the best case for grain growth in a PMS object is that of the nearby TTS TW Hya, which has been mapped at 7mm by Wilner et al. (2000) and analyzed recently by Calvet et al (2002) using detailed, self-consistent disk models. The result is that the fluxes and 7mm surface brightness profile are consistent with an outer disk where grains have grown to size of ~ 1 cm. This, and similar results on other PMS stars that should come in the near future, will provide much needed observational constraint to grain growth and planetesimal formation theories.

7. Summary

In this talk I have presented a summary of the properties of disks around pre-main-sequence stars, i.e., when the central objects have already accreted most of their final mass and have cleared most of the surrounding material from which they have formed. This stage of disk evolution is when planets can form. It is, therefore, of interest to know their properties and how they change during the PMS life of the stars, if we want to understand how planetary systems form and, in their turn, evolve.

Pre-MS disks are rich in gas. We know something about their shape, namely that in many cases they are “flared”, as expected for gas-rich disks in hydrostatic equilibrium. Masses are uncertain, and vary by more than two orders of magnitude for stars of similar properties. Assuming a gas-to-dust mass ratio of 100, we find disk masses of 0.003-0.3 $M_{\odot}$, with a rather constant ratio of disk to stellar mass of about 0.03, and again a large dispersion. Sizes are a few hundred AU, with a large spread, due in part to the variety of observational techniques used. Temperatures are consistent in most cases with disks being heated by irradiation from the central star. This is an area of fast progress, as better disk models (both of the thermal structure and of the chemistry) as well as observations of an increasing number of molecular species become available.

Stars of all mass have disks, from objects of ~ 3 -4 $M_{\odot}$ to brown dwarfs and planetary-mass objects. The exception are the more massive stars, that seem

Figure 7. Comparison of the observed values with model predictions in a plot of the 1.3mm flux versus the millimeter spectral index. Each curve is computed for disks having fixed values of the outer radius R_D and of the dust opacity slope β , as labelled; the disk mass decreases along the curve (from Testi et al. 2001). The observed points have been scaled to take roughly into account the difference in luminosity of the stars.

to lack significant disks. This is probably a result of the fast disk dissipation caused by a combination of photoevaporation by the stellar radiation of the outer disk and of viscous evolution of the inner disk. Less massive stars have typical disk lifetimes of a few million years. However, there are again large individual variations, and several stars retain their rather massive PMS disks at ages of 10 Myrs. We do not know yet what exactly determines the survival of an individual disk, even if we can guess that being located in a dense cluster or too close to a massive star is a bad idea.

Finally, I have briefly summarized the state of the research on grain growth during PMS lifetimes, which is considered the initial step toward the formation of planetesimals and planets.
